Abstract

We have developed an efficient algorithm based on the Genetic Algorithm(GA) for optimization of a model of a nonlinear system. Estimation of the interaction mechanisms among system components by using experimentally observed dynamic responses (timecourses) of some of the system components is generally referred to as "inverse problem". The S-system, which belongs to power-law formalism, is one of the best representations to solve such an inverse problem; the S-system is rich enough in structure to capture all relevant dynamics. In this paper, for the purpose of solving the inverse problem, we introduce the GA and propose an efficient procedure for the estimation of large numbers of parameters in the S-system formalism. We applied our method to a simple oscillatory system and a gene expression network.

1 INTRODUCTION

In the case where the details of the molecular mechanism that govern interactions among system components (state variables) are not well known, however, how do we mathematically model such complex processes?; most of these processes are nonlinear. Description of these processes requires a representation that is general enough to capture the essence of the experimentally observed response. One of the best approaches that satisfy this requirement is the "S-system" (Savageau, 1976, Voit, 1991, Tominaga and Okamoto, 1998) which is a type of power-law formalism because it is based on a particular type of ordinary differential equation in which the component processes are characterized by power-law functions;

$$\frac{dX_i}{dt} = \alpha_i \prod_{j=1}^{n} X_j^{g_{ij}} - \beta_i \prod_{j=1}^{n} X_j^{h_{ij}}$$
 (1)

where n is the number of state variables or reactants (X_i) , i,j $(1 \leq i,j \leq n)$ are suffixes of state variables. The terms g_{ij} and h_{ij} are interactive effectivations.

ity of X_j to X_i . The first term represents all influences that increase X_i , whereas the second term represents all influences that decrease X_i . In a biochemical engineering context, the non-negative parameters α_i and β_i are called rate constants, and real-valued exponents g_{ij} and h_{ij} are referred to as kinetic orders. The simple homogeneous structure of S-system has a great advantage in terms of system analysis and control design, because the structure allows analytical and computational methods to be customized specifically for this structure(Irvine and Savageau, 1990). However, the S-system formalism has a major disadvantage in that this formalism includes a large number of parameters that must be estimated $(\alpha_i, \beta_i, \beta_i)$ g_{ij} and h_{ij}). The number of estimated parameters in S-system formalism is 2n(n+1), where n is the number of state variables (X_i) . In this paper, we should propose an algorithm and procedures for the estimation(optimization) of large numbers of parameters (Okamoto et.al., 1997, Tominaga et al., 1996, 1999). The basic idea is as follows: the Genetic Algorithm (GA)(Baker, 1985, Goldberg, 1989, Davis, 1991) as a nonlinear numerical optimization method which is much less likely to be stranded in local minima. Furthermore, in order to find the skeletal structure (small-size system) of S-system formalism that matches the experimentally observed responses, some of the parameters $(g_{ij} \text{ and } h_{ij})$, absolute values of which are less than a given threshold value, are to be removed (reset to 0) during optimization procedures. By introducing this algorithm reffered to as structure skeletalizing (Tominaga and Okamoto, 1998, Tominaga et al., 1999), that optimized essential S-system model that matches the experimentally observed responses should be possible.

2 OPTIMIZATION TASK

When an adequate time-course of relevant state variable is given, a set of parameter values α_i , β_i , g_{ij} and h_{ij} , in many cases, will not be uniquely determined, because it is highly possible that the other sets of parameter values will also show a similar time-course. Therefore, even if one set of parameter values

^{*}To whom all correspondence should be addressed.

that matches the observed time-courses is obtained, this set is still one of the best candidates that explain the observed time-courses. Our strategy is to explore and exploit these candidates within the immense huge searching space of parameter values. In this optimization problem, each set of parameter values to be estimated is evaluated using the following procedure: Suppose that $X_{i,cal,t}$ is numerically calculated time-course at time t of state variable X_i and $X_{i,exp,t}$ represents the experimentally observed time-course at time t of X_i . Sum the relative error between $X_{i,cal,t}$ and $X_{i,exp,t}$ to get the total error f

$$f = \sum_{i=1}^{N} \sum_{t=1}^{T} \left\{ \left(\frac{X_{i,cal,t} - X_{i,exp,t}}{X_{i,exp,t}} \right)^{2} \right\}$$
 (2)

where N is the number of experimentally observable state variables, T is the number of sampling points of the experimental data. The problem is to find a set of parameters that minimizes f. The structure of the genome(design code) of each individual(each set of parameter values) in GA is shown in Figure 1. A genome(corresponds to one individual) contains a set of S-system parameters ($n \alpha_i s$ and $\beta_i s$, and $n \times n$ g_{ij} s and h_{ij} s) which forms an $n \times (2n+2)$ matrix. An individual represents one S-system model. Each small square in Figure 1 corresponds to each parameter that has a real value. We introduced the following coding for representing real numbers: a 32bit unsigned integer format within a given searching region, that is, each dimensional region to be searched is divided into 2³² discrete points and is numbered using a unsigned integer. A real value within a searching region is represented by scaling a unsigned integer with offset.

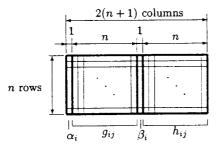

Figure 1: Design code of an individual; two n vectors of α_i and β_i , and two $n \times n$ matrices of $n \times n$ g_{ij} and h_{ij} form $n \times (2n+2)$ matrix. This matrix represents one S-system model.

2.1 GENETIC ALGORITHM

The optimization procedure in GA is as follows:

(0) Prepare a set of experimentally observed timecourse data of n state variables. The number of sampling point(T) is common for each state variable. Determine the number of individual P, maximum limit of generation G_{max} , search regions for $\alpha_i(\beta_i)$ and $g_{ij}(h_{ij})$, initial mutation rate m_0 , and the threshold of structure skeletalizing S for g_{ij} and h_{ij} .

- (1) P initial guesses (P sets of α_i , β_i g_{ij} and h_{ij}) are randomly created. Each matrix element of an individual (Figure 1) has a real number and is randomly set within a given searching region.
- (2) Evaluate each individual. Solve a simultaneous differential equation (Equation 1) for each individual, and calculate total error f using Equation 2. The fitness of each individual is calculated as the reciprocal of total error f. Within the group of P-individuals in every generation, select the individual having the largest fitness(elite individual) and check whether the total error f of this individual is less than a given threshold value of convergence. If the largest fitness converges or the number of generations is beyond the specified count G_{max} , or if the fitness of elite individual does not change during $G_n(< G_{max})$ generations, exit the loop and terminate. The elite individual is reported as the best matched model.
- (3) Otherwise continue searching by introducing genetic operations (crossover and mutation). Elite strategy is introduced over the generations.
- (4) With the exception of the elite individual, the design code of each child is created based on the design codes of two parents. Two parents are selected by the roulette-wheel selection with ranking strategy. For each individual, the probability to be selected (p_i) is calculated by the following equation:

$$p_{i} = \frac{1}{N} \left(\eta^{+} - (\eta^{+} - \eta^{-}) \frac{i-1}{N-1} \right) \qquad (1 \le i \le N)$$
(3)

where N is the number of individuals, η^+ and η^- are the maximum and minimum probability of selection. We set the η^+ and η^- to 1.1 and 0.9, respectively.

- (5) From the two selected parents, each matrix element of the child is alternatively chosen from the corresponding elements of either parent at the same probability. Since the number of matrix elements is 2n(n+1), where n is the number of state variables, this operation corresponds to the 2n(n+1)-1 point crossover. The value of each matrix element is not changed by crossover.
- (6) Furthermore, miss-writing (mutation) is supposed to occurr at mutation rate m when the matrix elements of the parents are copied to a child. We introduced Gaussian mutation in which average and distribution are defined by the original value and d, respectively. Set d to d_0 at the initial generation, and change the value according to the following conditions: (i)When the fitness of the elite individual does not change during G_m generations, change to $d_1(< d_0)$. (ii) After the change, if the fitness of the elite individual does not increase during next G_d generations, change to $qd_0(q > 1)$. (iii) If the fitness is not improved during next G_d generations, the value of distribution d is returned to d_0 . (iv) When the fitness of the elite individual increase due to the (i)-(iii) strategies, the distribution d is reset to d_0 . The mutation rate m is

changed to k-times(k > 1) when the fitness of the elite individual does not go up during G_m generations.

- (7) By repeating the procedures (4)-(6), (P-1) children are created for next generation. One child is the elite individual whose design code is not submitted to the genetic operations.
- (8) Structure skeletalizing; i) The term g_{ij} (h_{ij}) , absolute value of which is less than a given threshold value (skeletalizing value) is reset to zero. ii) This procedure is performed at every specified generation and at the termination of optimization.
- (9) Return to step (2).

3 APPLICATIONS

3.1 OSCILLATORY SYSTEM

Figure 2(A) shows the calculated time-courses of X_1 and X_2 of the S-system(N = 2 in Equation 1), parameter values of which are shown in Table 1. Given these time-courses of X_1 and X_2 (Figure 2(A) is presented as experimental data($(X_{i,exp,t})$, N=2, T=50in Equation 2)), we examined whether our proposed optimization procedures could explore and exploit a set of parameter values which can provide the best fitted time-course shown in Figure 2(A). The major optimizing conditions are as follows: searching ranges are [0.0, 5.0] for α_i and β_i , [-3.0, 3.0] for g_{ij} and h_{ij} , $T = 50, P = 10000, G_{max} = 1000, G_n = G_{max}/2,$ $m_0 = 0.05$, $G_m = 20$, $d_0 = 4.0$ (for α_i and β_i), 1.6(for g_{ij} and h_{ij}), $d_1 = 0.5$ (for α_i and β_i), 0.2(for g_{ij} and h_{ij}), $G_d = 10$, q = 5, k = 1.01, and the structure skeletalizing are performed at every generation and the threshold value of which is 0.5.

Figure 2(B) shows the obtained time-courses under the above optimization condition. The obtained parameter values are listed in Table 2. Compared the time-courses in Figure 2(B) with those in Figure 2(A), the overshoot peak values of X_1 and X_2 in 2(B) is less than those in 2(A), and the time-courses after t = 1.0 (arbitrary unit) of X_1 and X_2 in 2(B) are more monotonous than those in 2(A). The total dynamic patterns in 2(B) are, however, very similar to those in 2(A); the average relative error between calculated (2(B)) and given time-courses (2(A)) per sampling point is 3.65% (see the column of algorithm A in Table 3). Since this result shows that the optimization method might be stranded in local minima, we have improved our algorithm in order to explore and exploit the better parameter space. In the above case, since the number of individuals in one generation is very large (P = 10000), most of the individuals the fitness value of which is small might be disappeared by ranking strategy, which leads to the survival of the large numbers of individuals which have very similar S-system parameters. In order to avoid this situation, we divided the individuals into many small groups. We made 9 small groups which consists of 100 inidividuals. The alternative algorithm is as follows: First, each small group independently

performs optimization according to the proposed algorithm except for P=100, $G_{max}=10000$. After the independent searching, 9 best individuals are obtained from each small group. Prepared 91 individuals except for 9 best individuals, we make the final group (the number of individuals (P)=91+9=100) which is allowed to the optimization according to the proposed algorithm $(P=100,\,G_{max}=10000)$. The total numbers of created individuals is, therefore, $9\times 100\times 10000+1\times 100\times 10000=10^7$, which is the same as in the case of one large group; $P\times G_{max}=10000\times 1000=10^7$.

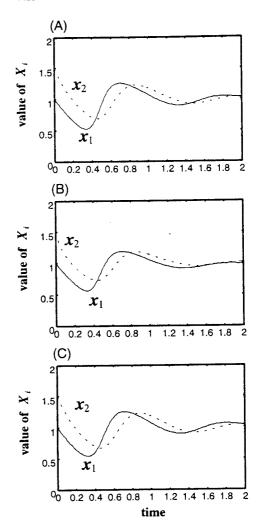

Figure 2: Given time-courses and obtained time-courses of X_1 and X_2 . (A), Given time-courses(parameter value are listed in Table 1); (B), obtained time-courses (a set of parameters is listed in Table 2.) (C), obtained time-courses (a set of parameters is listed in Table 4.) Initial values of X_1 and X_2 is 1.0 and 1.5 respectively. In (A), the number of sampling points of experimental data is 50 (T = 50 in Equation (2).)

The obtained parameter set by the revised algorithm

is listed in Table 4, and the calculated time-courses are shown in Figure 2(C). The oscillatory profile in Figure 2(C) is quite similar to that in 2(A); the average of relative error between calculated (2(C)) and given time-courses (2(A)) per sampling point is 1.39% (see the column of algorithm B). Compared the obtained S-system parameters (Table 4) with those in Table 1, the structure (sign and magnitude of parameter) is very similar. Table 5 shows the obtained results for optimization with the original algorithm (algorithm A) and with the revised algorithm(algorithm B). The values in the table show the average value of 30 trials with the corresponding algorithm. The values in the parentheses represent standard deviations. These results show the superiority of the revised algorithm(algorithm B) to the original one(algorithm A).

3.2 GENE NETWORK

Next, the proposed method was applied to determine a set of parameters of the S-system which represents a typical model of a gene network.

As a case study, we created several sets of time series data, shown in Figure 3, which were numerically calculated using the scheme shown in Figure 4(Savageau, 1998). The S-system parameters in Figure 4 are shown in Table 6. The time series data in Figure 3(A) were calculated with the condition that $\alpha_1 = 15.0$, $\alpha_4 = 8.0$ in Table 6, which corresponds to the situation in which both gene 1 producing $X_1(mRNA)$ and gene 4 producing $X_4(mRNA)$ are active (wild-type). In contrast, the time series data in Figures 3(B) and 3(C) were obtained under the condition that $\alpha_1 = 0$, α_4 = 8.0 and that α_1 = 15.0, α_4 = 0, respectively; Figure 3(B) shows the case of the disruption of gene 1(corresponds to $\alpha_1 = 0$), and 3(C) is the case of the disruption of gene 4(corresponds to $\alpha_4 = 0$). The optimization task is as follows: Can the proposed algorithm explore and exploit the best S-system parameters matching the observed time courses shown in Figure 3(A)-(C)?

We attemped to estimate part of the system parameters in Table 6. The targets of optimization are twelve parameters; $\alpha_1, g_{11}, \ldots, g_{15}, \alpha_4, g_{41}, \ldots, g_{45}$. These represent the interaction coefficients that give increasing effects of X_1 and X_4 (expression and regulation of mRNA), respectively. The major optimizing conditions are as follows: searching ranges are [0.0, 20.0] for α_i and β_i , [-3.0, 3.0] for g_{ij} and h_{ij} , T=50, P=5000, $G_{max}=400$, $G_n=G_{max}/2$, $m_0=0.004$, $G_m=10$, $d_0=4.0$ (for α_i and β_i), 1.2(for g_{ij} and h_{ij}), $d_1=0.5$ (for α_i and β_i), 0.15(for g_{ij} and h_{ij}), $G_d=10$, q=5, k=1.01, and the structure skeletalizing were performed at every generation and threshold value of which is 0.05.

At the 266th generation (CPU-time is about 11 hours), we found the parameter set $(\alpha_1, g_{11}, g_{12}, g_{13}, g_{14}, g_{15}, \alpha_4, g_{41}, g_{42}, g_{43}, g_{44}, g_{45})$ to be completely identical to that shown in Table 6. In an early step of total optimization (at the 78th generation), a model which reflects the same structure as the given model was obtained, as shown in Table 8. The differences in pa-

rameter values between Table 6 and Table 8 are not remarkable, indicating that the structure of the system was obtained by global searching in early stages of the optimization, and local searching (fine tuning of parameters) was performed after the 78th generation.

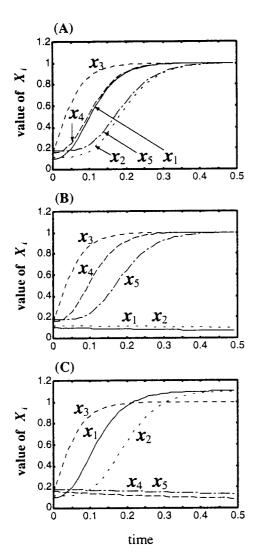

Figure 3: Time series data calculated from the S-system shown in Table 6; (A), wild type($\alpha_1 = 15.0$, $\alpha_4 = 8.0$); (B)disruption of gene $1(\alpha_1 = 0.0, \alpha_4 = 8.0)$; (C)disruption of gene $4(\alpha_1 = 15.0, \alpha_4 = 0.0)$; There are 51(sampling points) times 5(components) points in these time-courses data.

4 DISCUSSION

In the application to the gene network, the final optimized structure was found at the 266th generation and its essential structure was found at the 78th generation. The fitness value of the best model (obtained at the 266th generation) is 133.6. The relative error of

Table 7: Obtained results of optimization in gene network. The time for optimization was measured on Tempest 2 (Concurrent Systems Inc., Japan (processor:Alpha 21164A, 533MHz, SPECfp95: 20.1, SPECint95: 16.6))

Average relative error(%)	1.0×10^{-3}
Total explored generations	266
Time for optimization	39368sec

calculated time series data to the given data (Figure 3(A)-(C)) per sampling point is about 1.0×10^{-3} (%). The fitness value and relative error at the 78th generation is 3.86 and 3.45×10^{-2} (%), respectively. The fitness was remarkably improved during the 78th and the 266th generations, however, the relative error per sampling point decreased slightly (from 1.0×10^{-3} (%) to $3.45 \times 10^{-2} (\%)$). Estimation of parameters in the S-system using experimentally observed time-courses is generally referred to as inverse problem and these time-courses correspond to the restricted conditions for an inverse problem. Since the proposed algorithm proposes candidates (parameter sets) matching the restricted conditions, the best candidate can most likely be found by preparing more time-course data under the disruption and overexpressions in the gene network.
